Abstract

Reconstruction of extensive bone loss in the foot requires a set of strategies involving various surgical techniques and orthopedic devices. Semicircular Ilizarov external fixator combined with a structural homologous bone graft may be advantageous in pediatric patients. This case report describes the technique of reconstructing an extensive bone loss of the first metatarsal with osteodistraction and homologous graft in an immature skeleton. The combination of the external fixator and the homologous graft provided sufficient bone volume without recurrent infection, minimal complications, substantial length gain of the metatarsal bone, and improved soft tissue conditions. It is a viable treatment option for severe foot injuries in immature skeletons.

Introduction

Reconstruction of bone loss in the foot requires a set of strategies involving surgical techniques and orthopedic devices. Bone losses between 2 and 4 cm can be treated with an autogenous bone graft1,2. Bone grafts have a well-established role in orthopedic surgery, but filling metaphyseal defects is associated with complications that include postoperative pain and morbidity3.

In treating large bone defects, extensive grafts are often required, which is limited to the amount of autologous bone available. Furthermore, in skeletally immature patients, the choice of the autologous graft should consider the risk of damage to the growing physis and the amount of graft available. Thus, a structural homologous bone graft may be advantageous due to biocompatibility, the capacity for bone stock restoration, and potential of ligament reinsertion4.

There are a limited number of case reports and scientific articles regarding the reconstruction of bone loss in the foot using osteodistraction and homologous graft in pediatric patients. The aim of this case report is to describe the technique of reconstructing an extensive bone loss of the first metatarsal with osteodistraction and homologous graft in an immature skeleton for five years of follow-up.

Case Report

The patient and her legal guardian consented to this case report and signed the informed consent form. The study was approved by the Ethics Committee under registration CAAE n. 56135522.5.0000.0033.

A female patient, hit by a car at age five, suffered severe trauma to the left foot, large soft tissue injury, and exposed fracture Gustillo and Anderson IIIB. Returns to the outpatient clinic at the age of 11 to treat the left hallux shortening in the extended position, associated with scar retraction, great functional limitation, ability to walk, and difficulty wearing closed shoes (Figure 1). Reconstruction of bone loss was performed with osteodistraction and homologous graft according to the surgical procedure described below.
The patient was in dorsal decubitus under spinal anesthesia with a lateral cushion and tourniquet at thigh level. The external fixator Ilizarov semicircular (Figure 2) was placed with a planned assembly of three rings, one in the medial and middle foot wedge, one in the head remnant of the first metatarsal, and one in the proximal and distal phalanx of the hallux, fixed with 4.0mm Schanz pins for bone distraction and soft tissue elongation and arthrodiastasis. A zetaplasty incision was made to correct the scar retraction and deviation in the hallux extension. It was instructed to proceed with soft tissue elongation and bone 1mm per day, four times of 0.25mm in the two distal half-rings, ten days after surgery, for 60 days. The patient presented superficial soft tissue infection, treated with cefadroxil 500mg every 12 hours for ten days. After 90 days, the circular external fixator was removed, and weak bone regeneration was observed, improving the appearance of soft tissues and scar retraction (Figure 3). The patient was submitted to new surgery with a soft tissue incision, dissection by planes, and preparation of the receiving area (Figure 4). Metatarsophalangeal arthrodesis was performed without joint preparation, only decortication due to the poor quality of the joint, as described below. The tricortical iliac graft was removed from the mother, and the bone loss was filled with two unblocked plates and mini fragments. The patient evolved with a good appearance wound, mild dehiscence treated with dressings, and resolution of the soft part aspect. After six months of follow-up, good bone consolidation, no signs of infection, osteolysis, or loosening of materials were observed through clinical and radiological evaluation (Figure 5). The patient reported high satisfaction with the surgical, aesthetic, and functional results and mild pain evaluated through the Visual Analog Pain Scale. In the five years of follow-up (Figure 5) of the initial approach, the patient does not want...

Discussion

In the scientific literature, there are few studies on restoring complex foot injuries in immature skeletons(6). Osteogenic distraction by the Ilizarov method is one of the most used techniques in treating fractures with bone loss. This method includes a circular external fixator and the translocation of a bone segment from a healthy donor area to the bone loss region(7). The combination of osteogenic distraction and zetaplasty allows the skin and soft tissue elongation to be achieved, avoiding the recurrence of contractures and the use of skin grafts(8).

In reconstructing bone loss in immature skeletons, the use of iliac bone graft remains the “gold standard”(9). However, in this case, the skeletal immaturity, the possibility of growing physis involvement, the scarring in the graft donor area, and the limited amount of material were considered negative points in the choice of autologous graft. Thus, the homologous graft was chosen considering the disadvantages presented, the absence of a bone bank available in the region and the possibility of the mother as a donor of the bone graft.

Canzi et al.(10) reported two successful cases of large cranial loss reconstruction using structural homologous bone grafts in pediatric patients. The authors highlighted that the risk of infections was minimal when compared to high quality, biomechanical stability, and absence of evident interference in long-term growth.

In a recent study, Jogani et al.(6) reported the bone reconstruction of the first metatarsal after severe foot trauma using the external fixator associated with the Masquelet technique in a 62-year-old male patient with injury of the first metatarsal and proximal part of the phalanx, after 24 months postoperatively satisfactory functional results were obtained and the total incorporation of the fibular graft.

In this study, the combination of osteogenic distraction associated with the homologous graft in an immature skeleton presented satisfactory results, without recurrent infection, with minimal complications from external fixators and substantial length gain of the metatarsal bone.

Conclusion

The reconstruction of extensive bone loss of the first metatarsal with osteodistraction and homologous graft in an immature skeleton was able to promote an almost total restoration of bone length and improve soft tissue conditions, being a viable treatment option in severe foot injuries in pediatric patients.
